1. Bootstrap Your Dev Environment on Mac OS-X in Minutes

Just tell me what to run, I don't have time for this README.

```
curl -fsSL 'http://sw.in/pu-bootstrap' | /usr/bin/env bash
```

Alternatively, for a finer-grained control of your installation, do the following:

```
git clone https://github.com/kigster/pullulant
cd pullulant
./pu -PR
```

- -R will run every installer (which are executable modules that typically install a particular thing), and

- `-F` will include every feature set (which is a collection of brew/bash-it/etc plugins or packages, grouped together by a common theme, i.e. "ruby" feature would include ruby-development related brew packages, casks, bash-it plugins, etc).

For more information, please see the full usage below:

```
$ pu -h
```

1.1. Full Help

```

Pullulant (or just pu) (Version 1.9.0) Git Rev: 6bf092c
OS-X Installer for Web Devs, MIT License | (c) 2015-2016 Konstantin Gredeskoul
https://github.com/kigster/pullulant http://kig.re

Usage:
pu { -R | -r 'runner runner ...' } { -s 'runner runner ... ' }
  { -F | -f 'feature feature ...' }
  { -BCFHIKLNPRSTUZhiklmnopqvy }
  { -e 'expression' }

Eg.
pu -l # list all available runners
pu -t # list all available features
pu -RF # install all runners/features
pu -r homebrew -f ruby # install homebrew with ruby specific packages

Getting Help:
-h paginated help message in full color
-H non-paginated help message in full color
-X non-paginated help message in pure ASCII
-d show advanced usage with expressions
-D show remaining runners after each runner
-E show usage examples

Runners:
Runners are modules that do certain work, i.e. install software, or remove it.
They are located in two folders: ./helpers and ./installers and are divided
logically into 'Helpers' and 'Installers' correspondingly. NOTE: each
runner is a bash script with a bash function matching scripts name.

Installers are the modules that install something new and
are to be included in the list of a complete install. They are
ordered. For example 'install_ruby' installs ruby and dependencies.
To run ALL installers, use the -a flag.

Helpers are similar to installers, except they are not run as
part of the full install. They must be invoked by name directly.
Because of that, helpers tend to be more diverse in nature: some
uninstall things, fix things, and so on.

But collectively, helpers and installers are just 'runners' and are the 'units'
of pullulant's magical universe...

-R full install: executes each runner from the './installers' dir
-r 'runner runner ...' run specific installer(s) and/or helper(s) in the provided order
-s 'runner runner ...' skip a specific installer otherwise included with either -R or -r
-l list available installers and helpers

Runner-specific Flags:
-V postgresql-version
  If provided, this version is installed, otherwise the latest
  is installed. Valid versions are .

-b ruby-version Override ruby version to install specified in packages

-S [S]proutwrap is disabled during the full install
-B [B]rew-upgrade is disabled during the full install
-P No backup[P] for rsync of bash and zsh files (default is to backup)
-h When installing ruby's NOKOGIRI library, do NOT set
  NOKOGIRI_USE_SYSTEM_LIBRARIES to 1 when -h is set
-m When installing term themes, prefer the small selection of
  listed color schemes, instead of installing the entire set.

Features:
Features are a set of brew packages, bash-it plug-ins, completions
and aliases, defined a particular theme. For example, ruby feature
enables bash aliases and completions related to all ruby
development tools. It also adds a ruby-specific set of brew
formulas and casks - such as RubyMine IDE, etc.

-f 'feature feature ....' Merge packages from a provided set of features.
-F Merge ALL available features, currently:
-t List available features

Error Handling:
Default error handling is pessimistic: installer stops upon any
error code returned from a single 'run' statement.
You can control error handling at two levels:

-i [i]gnore errors and continue to the next 'run' statement.
-I Stops running the current installer that produced an error, skips
  the rest of it, and continues to the next installer. For example,
  in this mode, if one homebrew package fails to install, the rest
  of homebrew installer will be skipped, and the next installer in
  the run list will begin.

Homebrew:
-o f[o]rce - applies to some installers, ie. brew (--force) and
  zsh (overwrites current shell to ZSH). Also some rsync
  installers may behave differently with -f.
-C -F -L flags allow picking specific subset of the install.
  The flags can mix. Adding all three is the same as adding none.
-L Only [L]ink packages configured for brew linking
-C Only [C]asks are installed from a configured list
-U Only form[U]las are installed from a configured list

  These apply to all brew commands:
-y [R]einstall each formulae during brew install
-k Relin[K] all brew formulas/casks during install

Zsh
-Z Change the default shell to ZSH and install 'oh-my-zsh'

Interaction and Output Control:
-N run some parts interactively, letting user confirm install
-su[p]press pretty section headers for more compact output
-q [q]uiet mode: stop printing commands before and after run.
-v [v]erbose - show each command's output, and add -v to some
  dry-ru[n] - print commands, but don't actually run them.

```

1.2. Pu Examples

Examples:

- Run a complete installer using a union of all available features with default output and error handling options:

```
pu -RF
```

- Install everything with the default (small) set of packages, but with an interactive check:

```
pu -RN
```

- Install everything with specific features and plugins enabled suitable for ruby, python and node development, as well as install services used in web development such as nginx, haproxy. Also, override ruby version with 2.3.0.

```
pu -R -f 'ruby python nodejs web aws docker' -b 2.3.0
```

- Use a helper (not an installer) to wipe clean and reinstall postgresql from brew, create a new UTF8 database, and ensure it's running after:

```
pu -r reinstall-postgres
```

- Wipe and reinstall homebrew, and install ruby-specific packages:

```
pu -r 'brew-wipe homebrew' -f ruby
```

- Repair homebrew, and install additional python packages:

```
pu -r 'brew-repair homebrew' -f python
```

- When installing brew packages, install formUlas only (-U), use --force (-o), and show verbose output (-v) without section headers (-p):

```
pu -r homebrew -o -U -p -v
```

- Install everything, minus sprout-wrap, with all of the available features.

```
pu -RFS
```

Debugging

`-e expr` evaluate expression in the context of pullulant post loading. This can be useful if you are developing / debugging the code.

For example, it allows you to evaluate any function that 'pu' loads into the bash space. Some examples - here we are evaluating library function `pu-installers()` which returns an array of all installers found in the folder.

```
pu -e pu-installers
```

Next, we can print every pu- related function loaded into memory:

```
pu -e 'set | grep "^pu-"'
```

2. Pu-what?

"Pullulant" is Latin for "Sprout". [Sprout-Wrap](#) was an inspiration for this install, as well as initially a large chunk of it, so the names gives credit where credit is due. As pullulant became more mature, the role of SproutWrap in the install process shrunk significantly, and eventually it will be removed completely.

3. Why Should I Use This?

This project is the basis for setting local dev environment of several San Francisco startups and independents. It captures the setup that originated as a small wrapper around [Sprout-Wrap](#) cookbook. But the cookbooks were too small and too brittle, and kind of difficult to fix (see appendix 1). So the shell script grew.

Now Pullulant combines hundreds of small steps into modular chunks that run one after another as part of a fully automated (even unattended) setup of the development environment. This is a great setup for projects involving building javascript, nodejs, ruby, python, C/C++, or even Arduino applications on Mac OS-X. This installer condenses a ton of personal experience and taste and merges it with that of Pivotal Labs. It's design gives you an easy way to use modules that can be run all at once, or one at a time.

The installer relies on [HomeBrew](#), [Sprout-Wrap](#), and about 3K lines of bash scripting to deliver your shell goodies to the door, all while customizing your environment to look like and serve you, the oh-mighty-powerful Developer, with all of it's shine. Try it! :)

I mean—just check out the sexy BASH prompt (based on the 'Powerline Multiline' theme and "Bash-It" framework) that you will get after running it :)

4. Pre-Install OS-X Preparation

1. Run `xcode-select --install` to make sure you have dev tools (although installer will still run it in the beginning)
2. Run OS-X Updates if any, and reboot if requested.
3. Go to *System Preferences / Sharing*, unlock the panel and set the hostname of your system, if it's currently set to a default.

4.1. About your OS-X user

shared resources used by the Homebrew, such as files under `/usr/local`, will change ownership to the user running this installer, with full `xwr` permissions for user and the group. This is so that the effects of any previously run `sudo brew` nuisance are neutralized.

Typically your group will be `staff`. Whatever group you are, that group is applied to the folder list defined in config (`/usr/local` and `/var/chef`), with permissions also reset to `xwr`. The idea is that this move should permit multiple co-existing users to share `/usr/local` and `/var/chef` at the same time.

Note that the current OS-X user must be configured as "Admin" on the Mac, and upon entering their password after the first request for `sudo`, the user will be modified to allow password-less `sudo` access for the duration of the script. At the end of the script, that access is removed.

You can use the helpers to enable/disable password-less `sudo` in your environment, by running `./pu -r sudo-enable` or `./pu -r sudo-disable`.

5. Install

1. If you don't already have SSH keys setup on this machine, now is the time: `ssh-keygen -t rsa -b 4096 -C "${USER}@${HOSTNAME}"; cat ~/.ssh/id_rsa.pub | pbcopy`
2. Add the new SSH key to the Github settings page: <https://github.com/settings/ssh>
3. Run the following installer:

```
curl -sSL https://raw.githubusercontent.com/robbyrussell/oh-my-zsh/master/oh-my-zsh.sh
```

6. After a Successful Install

- Reboot (required after the first successful install!) or you may get weird Security Agent errors.
- Open System Preferences, Security & Privacy, choose Privacy tab and unlock the lock at the bottom. After that choose Accessibility and then check "ShiftIt" application.
- Search in Spotlight, and start the following apps:
 - iStat Menus — click install when it comes up
 - Alfred 2

7. Understanding the Installer

Whether or not installer fully succeeded, you will, very likely, have folder `~/workspace/pullulant` where the installer resides. If you `cd` into that folder, you can then run `pu` script with various options to install more things, to clean postgresql, etc.

In fact, `pu` comes with a whole bunch of modules that are meant to be part of the installer, but also a bunch that are meant

to be used only when needed. Hence the terminology: `installer` vs `helper`.

See `pu -h` for more information, or scroll down to the section [Driving the Installer](#).

8. What's Installed

8.1. Languages

This setup is tailored for web application development, and its default set of packages is definitely biased towards ruby, installing both `rbenv` and `ruby-build`.

That said, tools such as `pyenv` are also installed, which makes installing multiple versions of `python` a breeze. Similarly, `npm` and `bower` are both installed by default.

8.2. Developer Necessities

- `iTerm2`—mandatory replacement for `Terminal` :)
- `Shift+Cmd+←/→`—Use `Ctrl-Option-Cmd` with arrows to quickly align windows on the screen.
- `iStatMenus`
- Typical services needed for building web applications:
 - `PostgreSQL 9.5`
 - `nginx`
 - `haproxy`
 - `Redis`
 - `memcached`
 - `ElasticSearch`
 - `AWS CLI`
 - `CMake`
 - `rsync`

8.3. Git

- Git aliases
- `hub` tool for GitHub with autocompletion on `zsh`
- Git scripts for pair programming `git pair`
- Git global defaults used by professional developers
- GitX Application

- Github Application

8.4. Editors & OS-X Applications

- RubyMine (JetBrains ruby IDE)
- WebStorm (JetBrains JavaScript IDE)
- CLion (JetBrains C++ IDE)
- vim
- Github's Atom
- TeamViewer for remote pair programming
- Docker toolbox + Kitematic
- VirtualBox
- Slack
- GitX

8.5. Shells

- Bash and Bash Completion are both installed
- Zsh and Oh-My-Zsh are installed, but no changes to the default shell are made ~~unless~~ unless -z flag is specified. In which case zsh is setup as a default shell.

8.6. Programming Fonts

- Powerline Fonts for the iTerm2 are installed, so that you get a great choice of coding fonts on a Mac. Powerline fonts are also required if you want to use 'reinvent-one' zsh prompt theme.

8.7. Google

- Chrome
- Drive
- Hangouts

9. Driving the Installer

```
$ ./pu -h
```

You should inspect the configuration and packages defined in two files:

- `lib/pu-config`
- `lib/pu-packages`

Variables with names starting with `var_` can be overridden before running the script. So can all the variables set in the `pu-packages` file, such as which brew formulas or casks to install.

11. Appendix

1. SproutWrap is difficult to fix when it breaks. For each sprout-something cookbook you must fork it first, fix the problem, then fork sprout-wrap, point to your fixed version in the Cheffile, then run it your forked version, and also maintain it until Pivotal merges your changes. Just not really that awesome of a process.
